(Received 24 July 1995)

Fluorinate glasses containing 1,2,3,4 ErF\(_4\) mol \( \% \) were prepared in a dry box under argon atmosphere. Absorption, Stokes luminescence (under visible and infrared excitation), the dependence of \( t_{1/2}^{1+} \) and \( t_{1/2}^{3+} \) lifetimes with Er concentration, and upconversion under Ti:sapphire laser excitation at \( \lambda = 790 \) nm were measured, mostly at \( T = 77 \) and \( 300 \) K. The upconversion results in a strong green emission and weaker blue and red emissions whose intensity obeys a power-law behavior \( I \sim P^\eta \), where \( P \) is the infrared excitation power and \( \eta \) = 1.6, 2.1, and 2.9 for the red, green, and blue emissions, respectively. The red emission exponent \( \eta \) = 1.3 can be explained by a cross relaxation process. The green and blue emissions are due to excited state absorption (ESA) and energy transfer (ET) processes that predict a factor \( \eta \) = 2 and \( \eta \) = 3 for the green and blue emissions, respectively. From transient measurements we concluded that for lightly doped samples the green upconverted emission is originated due to both processes ESA and ET. However, for heavily doped samples ET is the dominant process.

I. INTRODUCTION

There is a great interest in the study of rare-earth doped heavy metal fluoride glasses. These materials present a high transparency from UV to IR region; they can be easily prepared and a relative high concentration of transition metal and rare earth can be incorporated into the matrix.\(^{1}\) Due to low multiphonon emission rates, rare-earth doped fluoride glasses present large upconversion efficiencies and fluorozirconate fiber lasers have been reported.\(^{2}\)

Besides the well-known zirconates glasses several compositions based on indium fluoride have been studied.\(^{3}\) Compared to fluorozirconates glasses, these compositions present higher transparency in the mid-infrared range (up to 8 \( \mu \)m) - lower multiphonon emission rates and are also more stable against atmospheric moisture.\(^{4}\) The spectroscopy of Eu\(^{3+}\) and Gd\(^{3+}\) doped fluorinate was studied showing evidence of Eu-Eu and Gd-Eu energy transfer.\(^{5}\) Upconversion of fluorinate glasses doped with Pr\(^{3+}\) (Ref. 5) and Er\(^{3+}\) (Ref. 6) have been reported. In a previous work,\(^{6}\) some of us studied upconversion using a red laser (\( \lambda = 647 \) nm) to pump the Er\(^{3+}\) ions from the ground state to \( ^{4}I_{15/2} \) - Er\(^{3+}\) doped fluoride glasses conventional spectroscopy\(^{7,8}\) and upconversion\(^{9,10-12}\) have been studied very much lately. Upconversion have also been studied in many other glass types doped with Er\(^{3+}\), like silicate,\(^{13}\) fluoride,\(^{14,15}\) tellurite,\(^{16-18}\) oxide,\(^{19}\) chloride\(^{20}\) and others. A comparative study between fluoride and many others glasses shows that the superior upconversion emission is caused by their lower phonon energies.\(^{21}\)

In the present work, we report results of absorption, fluorescence, lifetimes measurements and upconversion measurements in Er\(^{3+}\) doped fluorinate glasses. The upconversion was studied by using a Ti:sapphire laser pumping the \( ^{4}I_{15/2} \) level. The results obtained in this work are substantially different from the ones obtained by pumping the \( ^{4}I_{13/2} \) level and provide a much better understanding of the upconversion mechanisms involved.

II. EXPERIMENT

Fluoride glasses with bath compositions 20ZnF\(_2\)-20SrF\(_2\)-2NaF-16BaF\(_2\)-6GaF\(_3\)-36-x\( \times \)InF\(_3\)-xEr\(_3\) with \( x = 1, 2, 3 \) and 4 mol % were prepared. The concentration range (1-4 \%) corresponds to 2.0-8.0 \( \times \)10\(^{20}\) Er ions/cm\(^3\). The mixture was heated in a platinum crucible at 800 °C during one hour for melting and at 850 °C for fitting, both treatments were performed in a dry box under argon atmosphere. The melt was cast into a preheated mold at 260 °C and slowly cooled down to room temperature. The samples were cut and polished into a parallel piped shape. The absorption paths of the samples were 2.07 mm, 1.77 mm, 2.01 mm, and 1.43 mm for concentrations 1,2,3, and 4 mol %, respectively.

The emission spectra (both conventional or Stoke luminescence and upconversion or anti-Stokes luminescence) were analyzed using a SPEX 1403 double monochromator equipped with RCA 31034 photomultiplier, connected to a PAR-128 lock-in amplifier. The infrared radiation (at 1500 and 970 nm) was detected by using a nitrogen cooled Judson 516-D detector. The Stokes luminescences were obtained by pumping the Er\(^{3+}\) with a Coherent Innova 400 Ar ion laser with a mirror for the UV lines (351 and 364 nm). Upconversion spectra were obtained by using a Coherent Miri-Basic Ti:sapphire laser at \( \lambda = 790 \) nm (used in cw mode), resonant with the \( ^{4}I_{15/2} \rightarrow ^{4}I_{13/2} \) transition. Lifetimes were measured by chopping the cw pumping beam with a mechanical chopper.

and by signal averaging the resulting fluorescence decays on a Hewlett Packard digital oscilloscope.

III. RESULTS AND DISCUSSION

A. Stokes emission and lifetimes measurements

By using the absorption data the energy level diagram for Er$^{3+}$ fluorindate glass was determined. Table I shows the energy (cm$^{-1}$), peak cross section and radiative lifetime of the most important energy levels. These calculations were carried out by using the Judd-Ofelt theory; the complete data with Judd-Ofelt parameters, transitions probabilities, branching ratios, radiative lifetimes, and peak cross sections for stimulated emission can be found in Ref. 9.

The Stokes emission (conventional luminescence) spectra for the 3 mol % sample are shown in Fig. 1 and 3. Figures 1(a) and 1(b) show the visible Stokes emission obtained by pumping the sample with UV radiation from the Ar laser. The main laser lines are at 351 and 364 nm, the second one is in resonance with the $^4G_{9/2}$ level. These spectra show three main groups of lines (blue, green, and red) that appear also in the absorption spectrum and correspond to the following transitions: $^5G_{9/2} \rightarrow ^4I_{15/2}$, $^2H_{11/2} \rightarrow ^4I_{15/2}$, $^4F_{5/2} \rightarrow ^4I_{15/2}$, and $^4F_{5/2} \rightarrow ^4I_{15/2}$. The line centered at 12 000 cm$^{-1}$ corresponds to transition $^5G_{9/2} \rightarrow ^4I_{15/2}$. The 300 K spectrum [Fig. 1(a)] also shows transitions $^4I_{15/2} \rightarrow ^2H_{11/2}$, $^4I_{15/2} \rightarrow ^4G_{9/2} \rightarrow ^4I_{15/2}$, and $^4I_{15/2} \rightarrow ^4G_{7/2} \rightarrow ^4I_{15/2}$. These transitions are indicated in process (a) in Fig. 2. As the $^2H_{11/2}$ level is thermally populated its fluorescence disappears at low temperatures. The peculiar feature of these spectra, both at 300 and 77 K, is that the blue emission is much more intense than the red one. The opposite is found, for instance, in ZBLA (ZrF$_2$-BaF$_2$-LaF$_3$-AlF$_3$) glass. It is also remarkable that the green emission increases by about one order of magnitude when the sample is cooled to 77 K. Figures 3(a) and 3(b) show the infrared Stokes emission spectra from 13 000–6000 cm$^{-1}$ (corresponding to 0.8–1.7 µm), obtained by pumping with the 488 nm radiation from the Ar laser [see also process (b) in Fig. 2]. It is interesting to observe that at 77 K, the $^4S_{3/2} \rightarrow ^4I_{15/2}$ luminescence is more intense than that of $^5I_{15/2} \rightarrow ^4I_{15/2}$ transition and the transition $^4S_{3/2} \rightarrow ^4I_{11/2}$ cannot be seen at 300 K. This is a consequence of the growth of the $^4S_{3/2}$ population when the temperature decreases as shown by relative increase of the 547 nm peak in Figs. 1. The peak observed in Fig. 3 indicated by an asterisk was not identified as an Er$^{3+}$ transition.

FIG. 1. Visible emission spectra of the 3 mol % sample at (a) 300 K and (b) 77 K. In part (b) the vertical scale is 12 times larger than part (a). The spectra were obtained by pumping with $\lambda \sim 355$ nm radiation. Unless when indicated, all the peaks are related to transitions from excited states to the ground state $^4I_{15/2}$.
The fluorescence decays originated from the 4f<sub>11/2</sub> and 4f<sub>15/2</sub> levels, were obtained by pumping the 4f<sub>19/2</sub> Er<sup>3+</sup> level by using infrared radiation (λ<sub>λ</sub> = 790 nm) from a Ti:sapphire laser. Level 4f<sub>19/2</sub> has a very short lifetime (of the order of tens of microseconds) due to fast nonradiative decay to 4f<sub>11/2</sub>. Thus the 4f<sub>19/2</sub> lifetime is negligible compared with 4f<sub>11/2</sub> radiative lifetime which is about 800 µsec as shown in Table II. Consequently, by taking the same arguments used for 4f<sub>11/2</sub> fluorescence, 4f<sub>11/2</sub> lifetime can be determined by analyzing its fluorescence decay under λ<sub>λ</sub> = 790 nm excitation [process (c) in Fig. 2]. However, we cannot use this argument to explain the 4f<sub>13/2</sub> fluorescence (using λ<sub>λ</sub> = 790 nm) because the decay times 4f<sub>11/2</sub> → 4f<sub>13/2</sub> and 4f<sub>11/2</sub> → 4f<sub>15/2</sub> are comparable. The fluorescence temporal behavior can be obtained from the rate equations for populations n<sub>i</sub> and n<sub>j</sub> of level 2 (4f<sub>11/2</sub>) and level 1 (4f<sub>13/2</sub>), as indicated in Fig. 2, given by

\[
dn_1/dt = \sigma_{\text{pump}} n_3 - A_{21} n_1,
\]

\[
dn_3/dt = A_{13} n_3 - A_{23} n_3,
\]

\[
dn_2/dt = A_{23} n_3 + A_{31} n_3 - A_{11} n_1,
\]

where \( \sigma_{\text{pump}} \) is the absorption cross section for the transition from level \( i \) to \( j \), \( \Phi \) the incident pump flux for λ<sub>λ</sub> = 790 nm, \( A_{ij} \) is the partial relaxation rate from level \( i \) to \( j \) and \( A_1 \) the total relaxation rate from level \( i \) given by \( A_1 = \sum A_{ij} \). We should remark that Eqs. (1) are valid only at low excitation power so that upconversion terms can be neglected. By reminding that \( A_{23} A_{13} \), the \( A_{23} \) term in Eq. (1b) can be neglected for longer times (\( > 1/\lambda A_1 \)). Also the radiative decay term \( A_{21} \) in Eq. (1c) can be neglected because almost all ions decay nonradiatively to level 2 (4f<sub>11/2</sub>). With these simplifications the \( n_2(t) \) population decay (4f<sub>11/2</sub>) is given by a single exponential and \( n_1(t) (4f<sub>13/2</sub>) \) by a double exponential:

\[
n_2(t) = N_2 e^{-\lambda_2 t},
\]

\[
n_1(t) = \frac{A_2 N_1}{A_1} \left( e^{-\lambda_1 t} - A_1/A_2 - e^{-\lambda_2 t} \right),
\]

where \( N_1 = \sigma_{\text{pump}} N_3 / A_{13} \), \( N_2 = A_{23} N_3 / A_{13} = A_2 N_3 / A_1 \), and \( A_1 = A_{21} / N_1 / A_{13} \). The 4f<sub>11/2</sub> lifetime \( \tau_1 = 1/A_1 \), was obtained by fitting the 980 nm fluorescence decay with an exponential curve. By using this \( \tau_1 \) value as a fixed parameter, the 4f<sub>13/2</sub> fluorescence decay at \( \lambda = 1.5 \mu m \) was fitted by a double exponential in order to determine the lifetime \( \tau_2 = 1/A_2 \). Figure 4 shows the experimental fluorescence decays of levels 4f<sub>11/2</sub> and 4f<sub>13/2</sub> with fits which agree well with Eq. (2b). The ratio (\( A_1/A_2 = 0.81 \)) is in good agreement with the factor 0.80 obtained in the fit.

In solids doped with rare-earth ions, the experimentally observed decay rate is a sum of three rates: a radiative decay \( (W = \tau^{-1}) \) whose theoretically calculated values are given in Table II), a multiphonon emission rate \( W_{\text{ph}} \) and a rate due to luminescence quenching \( W_q \) (also called concentration quenching). \( W_q \) depends strongly on the matrix phonon spectra and decreases exponentially with the effective phonon number \( (p = E/h \omega_{\text{eig}}) \), which is the well-known energy gap law. Raman spectra for ZBLAN (ZrF<sub>4</sub>-BaF<sub>2</sub>-LaF<sub>3</sub>-AlF<sub>3</sub>)

</table>
show a polarized band at 580 cm$^{-1}$. In fluoride glasses, the \( ^{4}S_{3/2} \) level at low temperatures and increases above 700 K. In Er doped crystals and glasses, the \( ^{4}S_{3/2} \) lifetime decreases with the concentration by two experimentally indistinguishable cross-relaxation processes (Refs. 14 and 21): \( ^{4}S_{3/2}(^{4}I_{15/2}) \rightarrow ^{4}I_{13/2}^{(2)} \) and \( ^{4}S_{3/2}(^{4}I_{15/2}) \rightarrow ^{4}I_{13/2}^{(1)} \). In the temperature range 77–300 K, for Er$^{3+}$ doped ZBLA, the \( ^{4}S_{3/2} \) experimental lifetime decreases by a factor of 3.0 for 0.5 and 2 mol % Er concentration, respectively. For temperatures lower than 100 K both samples, with 0.5 and 2 mol % Er have the same lifetime. The fact that 2 mol % has a shorter lifetime (for T>100 K) indicates that cross-relaxation processes play an important role. We observed similar results, i.e., a decrease by a factor of 1.1 and 2.7 for the 1 mol % and 3 mol % samples, respectively, when the temperature increases from 77 to 300 K (Table II). A similar behavior was also observed in tellurite glasses. The lifetime decreases strongly at high temperature but is almost constant at low temperature. The decreasing of the lifetime due to the increasing of the Er concentration (W$_{Er}$) was also studied. At T=300 K the \( ^{4}S_{3/2} \) lifetime decreases by a factor of 2.3 when Er$^{3+}$ concentration increases from 2.0 to 80X 10$^{20}$ ions/cm$^3$. In the same concentration range, we observed a decrease by a factor of 2.8 (Table II). As observed in ZBLA, tellurite, aluminate and gallate glasses, the \( ^{4}I_{15/2} \) and \( ^{4}I_{13/2} \) lifetimes have a much less pronounced dependence with both concentration and temperature than the \( ^{4}S_{3/2} \) lifetime. This is a consequence of the small number of phonons involved.

B. Upconversion process

Upconversion spectra have been measured by pumping Er ions with a Ti:sapphire laser at \( \lambda_p = 790 \) nm. Figures 5(a) and 5(b) show the spectrum for the 3 mol % sample at T=300 K and T=77 K, respectively. We observed a very intense green luminescence at \( \lambda \approx 547 \) nm corresponding to the thermally coupled \( ^{4}I_{15/2} \rightarrow ^{2}H_{11/2} \) transition, a red luminescence at \( \lambda \approx 650 \) nm due to the \( ^{4}I_{15/2} \rightarrow ^{4}F_{9/2} \) transition and a blue luminescence at \( \lambda \approx 467 \) nm from the \( ^{4}S_{3/2} \rightarrow ^{4}I_{15/2} \) transition. At 77 K (Fig. 5(b)) the green upconversion emission increases about one order of magnitude similar to the behavior observed in the visible Stokes emission spectra (Fig. 2). We also remind that in both visible and infrared Stokes emission spectra (Figs. 1 and 3) the intensity of all transitions coming from the \( ^{4}S_{3/2} \) level increase at 77 K indicating an increase of its population. In barium-thorium fluoride glasses, Yeh et al. observed an increase of the upconversion green emission by a factor of ~2.8 when the temperature is decreased from 300 to 77 K. The green and blue spectrum shapes are very similar to the ones obtained by pumping the \( ^{4}F_{9/2} \) level with a Kr ion laser (\( \lambda_p = 647 \) nm). However, the integrated blue emission is much smaller for pumping at \( \lambda_p = 790 \) nm than for pumping at \( \lambda_p = 647 \) nm.

To obtain more insight into the upconversion mechanisms the dependence of the upconversion intensity \( I \) was measured as a function of the incident pump power \( P \) at \( \lambda_p = 790 \) nm. All the experimental results can be fitted to a power-law behavior \( I \sim P^n \), with \( n = 2.1 \) for the green luminescence, \( n = 1.3 \) for the red luminescence, and \( n = 2.9 \) for the blue luminescence as shown in Fig. 6. A similar behavior for the green and blue luminescences was observed by Harris et al. in ZBLAN glasses and for the red emission in Te based glasses by Oomen et al.

![Emission Decay](image)

**FIG. 4.** Fluorescence decays from the \( ^{4}I_{15/2} \) level (\( \lambda = 1.5 \) m\u00b5) and \( ^{4}I_{13/2} \) level (\( \lambda = 0.973 \) m\u00b5) of the 1 mol % sample at 300 K. The line are the fitting for the \( ^{4}I_{15/2} \) and \( ^{4}I_{13/2} \) fluorescence, a single exponential decay (\( \tau = 8.1 \) m\u00b5) and a double exponential (\( \tau = 0.80 \) m\u00b5) respectively. These fits are in good agreement with Eq. (2).

![Upconversion Emission](image)

**FIG. 5.** Upconversion (anti-Stokes emission) spectra of the 3 mol % sample under infrared excitation (\( \lambda = 790 \) nm): (a) 300 K, and (b) 77 K.
FIG. 6. Log-log plots of the blue, green, and red upconversion emission intensities as a function of the infrared 790 nm excitation power for the 3 mol % sample.

As discussed previously, the \( \lambda_e = 790 \) nm excitation pumps essentially the Er\(^{3+} \) ground state to the level \( ^{4}I_{15/2} \) [process (a) in Fig. 7]. Two possible mechanisms for the green fluorescence can be envisaged: excited state absorption (ESA) and energy transfer (ET). As shown by process (b) in Fig. 7, ESA can happen from \( ^{4}I_{15/2} \) or \( ^{4}I_{13/2} \) states. The \( ^{4}I_{13/2} \) excited ion absorbs one more infrared photon, goes to \( ^{4}I_{11/2} \) and then decays to \( ^{2}H_{11/2} \). In the second case, the \( ^{4}I_{13/2} \) ion is promoted to the \( ^{4}I_{11/2} \) by absorbing another photon and then decay to \( ^{4}S_{3/2} \). In both cases the infrared laser is very close to resonance with ESA transitions (the detuning is less than 5%). However, the ESA absorption cross section of the second case is 2.3 times larger and appears therefore more probable.

In ET process, two \( ^{4}I_{15/2} \) excited Er ions exchange energy so that one of them (the donor ion) decays to ground state \( ^{4}I_{15/2} \) and the other one (the acceptor) is excited to \( ^{4}F_{3/2} \) which decays to \( ^{4}S_{3/2} \) [process (c) in Fig. 7]:

\[
^2{I}_{11/2}^* + ^4I_{15/2}^* \rightarrow ^2{I}_{15/2}^* + ^4F_{7/2}.
\]

FIG. 7. Er\(^{3+} \) energy level diagram and excitation mechanisms.

In both cases (ESA and ET) two infrared photons are needed to reach \(^4S_{3/2} \) which emits one green photon. This indicates an \( n = 2 \) exponent in the power-law behavior, that is very close to the experimental value \( n = 2.1 \).

The blue luminescence can also be explained by ESA and ET transfer processes. ESA is possible by the transitions \(^4I_{15/2} \rightarrow ^4G_{9/2} \) or \(^4F_{7/2} \rightarrow ^4G_{9/2} \) which decay to \(^4G_{9/2} \) [process (d) in Fig. 7]. ET may happen with the donor ion excited in \(^4I_{15/2} \) and the acceptor ion excited in \(^4F_{7/2} \). The donor decays to ground state and excites the acceptor to \(^4G_{9/2} \) level, which decays to \(^4G_{9/2} \) [process (e) in Fig. 7]. In both ESA and ET processes, three infrared photons are needed to excite one ion to \(^4G_{9/2} \) giving one blue photon. In this case, an \( n = 3 \) behavior is expected, in good agreement with the \( n = 2.9 \) experimental result. The blue upconversion luminescence is much weaker than the green one because the excitation mechanisms for the blue one involve states of shorter lifetimes and consequently having a lower population than the levels involved in the green luminescence.

In the case of the red upconversion, the experimentally observed \( n = 1.5 \) dependence can be explained by a cross relaxation process.\(^{16} \) The donor ion in \(^4S_{3/2} \) state decays to \(^4F_{7/2} \) while the acceptor ion in \(^4I_{15/2} \) state is excited to \(^4F_{7/2} \) [process (f) in Fig. 7]:

\[
^4S_{3/2} + ^4I_{15/2} \rightarrow 2^4F_{7/2}.
\]

one infrared photon is needed to pump the \(^4I_{15/2} \) state and two infrared photons are needed to reach \(^4S_{3/2} \) producing two red photons. This reasoning gives a \( n = 1.5 \) dependence close to the value \( n = 1.6 \) found experimentally.

We should remark that the green and blue upconversion results obtained with a red excitation (647 nm), close to \(^4F_{7/2} \) level, are different from the ones presented in this work. In this case the experiment gave also a power law but with \( n = 1.5 \) for the green emission and \( n = 1.6 \) for the blue one (results obtained for the 3 and 4 mol % samples). The discrepancy between the experimental values and the expected value \( n = 2 \) was attributed to saturation effects. The exponent \( n \) also varies when the same Er\(^{3+} \) energy level is pumped in different types of glasses. Experiments were done in oxide,\(^{16} \) chloride,\(^{17} \) ZBLAN,\(^{12} \) and in the present work, pumping the \(^4I_{15/2} \) using IR radiation around 800 nm. However in chloride glasses \( n = 2 \) was obtained for both green and blue luminescence and in oxide glass \( n = 1.5 \) was obtained for the green luminescence. This indicates that the upconversion mechanisms depend strongly not only on the pumping wavelength, which determines the pumped energy level, but also on the glass type.

We also studied the transient behavior of the green upconversion emission. The 1 mol % Er emission decay can be fitted by a double exponential with decay rates \( A_1 \) and \( A_2 \), where \( A_1 \) and \( A_2 \) are the total relaxation rates of the levels \(^4S_{3/2} \) and \(^4I_{15/2} \), respectively. The emission decays from the 3 and 4 mol % samples can be fitted by a single exponential with decay rate \( A_1 \) (decay time \( \approx 4 \) ms). This shortening of the \(^4S_{3/2} \) emission decay can be attributed to the ET pro-
process given by Eq. (3) as observed in LiYF$_4$:1% Er$^{3+}$. Consequently, we believe that for lightly doped Er samples the green upconversion is originated from both ESA and ET process. However, for heavily doped samples ET is the dominant process as observed in ZBLAN by Harris et al.\textsuperscript{12}

\textbf{ACKNOWLEDGMENTS}

This research was supported by Telebrás, Fapesp, Capes, CNPq prôgm RHAЕ-New Materials, Brazil, and the Departamento de Física, Universidad Industrial de Santander A. A. 678, Bucaramanga, Columbia.
