Prognostic factor

ABSTRACT

Aims: Several systematic reviews/meta-analyses of observational studies have demonstrated associations between circulating trimethylamine-N-oxide (TMAO) and cardiovascular, cerebral, and renal diseases, including mortality. However, causal roles for TMAO in these diseases are controversial. Interventions are lacking to show whether lowering TMAO in clinical trials could reduce the risks of these diseases. TMAO could still serve as a prognostic marker for the mentioned outcomes, but investigating this potential role requires robust methodologies. We conducted a systematic search and critical evaluation of published systematic reviews/meta-analyses in the field.

Data synthesis: We identified 27 systematic reviews/meta-analyses on the association between TMAO and stroke ($n = 7$), cardiovascular disease including cause-specific and/or all-cause mortality ($n = 14$), and other related outcomes ($n = 6$). The majority of the systematic reviews/meta-analyses found higher blood TMAO concentrations in patients who were positive for the outcomes. Primary studies included populations with multiple risk factors for the given outcomes and did not sufficiently account for potential confounders. Prospective studies examining associations between baseline TMAO and subsequent disease outcomes in healthy populations were entirely absent. Furthermore, we identified serious flaws in methods, conduct and reporting in the majority of the published systematic reviews/meta-analyses, thus leading to critically low confidence in the results.

Conclusions: High quality systematic reviews/meta-analyses examining the associations between TMAO and cardiovascular or cerebral disease are needed to examine potential causal and/or predictive roles of TMAO in these diseases. This study is registered at the International Prospective Register of Systematic Reviews (PROSPERO) (CRD42024534940).

1. Background

Trimethylamine-N-oxide (TMAO) is the product of N-oxidation of trimethylamine (TMA) by the hepatic Flavin-containing

monooxygenase-3 (FMO3). TMA is produced by the effect of gut bacteria on dietary choline, betaine, or carnitine. Consumption of red meat (rich in carnitine [1]), fish or sea-food, egg and dairy products [2–7] is associated with higher plasma TMAO concentrations, though not all

studies confirmed this association [2,8,9]. In healthy adults, plasma concentrations of TMAO range between 2.5 and 4.0 $\mu\text{mol/L}$. TMAO concentrations may increase by > 20 fold in patients on renal replacement therapy due to impaired glomerular filtration of TMAO [10,11].

In human observational studies, elevated plasma concentrations of TMAO have been associated with cardiovascular diseases [12–15], type 2 diabetes [16,17], impaired kidney function [18–20], and all-cause mortality [12,21]. Other studies have documented a lack of associations between TMAO and various cardiovascular diseases [22,23] or all-cause mortality, even in people with markedly high TMAO concentrations [11]. Of note, adjustment for renal function may abolish the associations between plasma TMAO and vascular or renal outcomes [24], suggesting that renal dysfunction is a major confounder in studies including adults with significant illnesses.

The basis for postulating a causal role for TMAO in atherosclerosis in humans has mainly been results from animal studies and statistical associations in observational human studies, both of which have inherent limitations with regard to causality conclusions. Some mechanisms that were discussed include vascular inflammation [25], thrombosis [26], macrophage foam cell formation [27], and enhancement of tubulointerstitial fibrosis and collagen deposition that causes renal injury [28]. Suppression of intestinal flora was found to reduce TMAO and abolished some of these changes in animals [27]. Direct extrapolation of these results to humans is not possible.

Interventions to lower plasma TMAO concentrations are not available and their potential health impact is unknown. Measuring TMAO concentrations has currently no application in clinical practice. Statistical associations between circulating TMAO and cardiovascular, cerebral, and renal diseases including mortality have been reported in multiple systematic reviews/meta-analyses with very similar objectives. In the present study, we aimed to conduct a systematic literature search to identify published systematic reviews/meta-analyses on the topic and to critically evaluate the body of evidence they provide.

2. Methods

The present study was conducted according to a priori protocol that was registered in the International Prospective Register of Systematic Reviews (PROSPERO) before starting the search (CRD42024534940). The population, intervention, comparator, and the outcomes of the present review are shown in Table 1. The paper was prepared according to the preferred reporting items for overviews of reviews (PRIOR) [29] (Supplemental Material).

Table 1
The population, intervention, comparator, and outcomes (PICO) of the present systematic review.

Population	Human subjects including healthy people (men and women), people with risk factors for vascular diseases, people with impaired kidney function, people recruited after a vascular event, people at risk for any of the study outcomes due to their previous morbidities such as diabetes, hyperlipidemia, hypertension, thrombosis, and anti-coagulants use.
Intervention (exposure)	Elevated concentrations of TMAO in plasma (EDTA or Heparin) or serum as defined by: 1)- a given cutoff (such as per 1 SD or a numerical cut-off) or 2)- an observed data-derived cutoff such as tertiles, quartiles, or quintiles.
Comparator	Concentrations of TMAO below the study-specified cutoff or in the lowest data-driven category.
Outcomes	Cardiovascular events (CVD), heart insufficiency/heart failure, myocardial infarction, stroke (ischemic and small vessel disease), atrial fibrillation, hypertension, other cerebral diseases, renal diseases and kidney dysfunction, composite outcomes often referred to as “major adverse cardiac and cerebrovascular event” (MACCE), major adverse cardiac events (MACEs), stroke- or CVD-specific death, and all-cause mortality.

2.1. Search and selection strategies

The study team with expert knowledge of the literature (including both exposure and outcome) developed and validated the literature search strategy. For the search in MEDLINE (on May 16, 2024), we used the keywords shown in Supplemental Table 1. The search in Web of Science and Cochrane Library is described in Supplemental Table 1. We screened the reference lists of potentially relevant studies and conducted an additional search in PROSPERO website to identify potentially relevant systematic reviews/meta-analyses. We additionally reviewed the study protocols (if available on any public domain) of the relevant systematic reviews/meta-analyses publications and evaluated the consistency in the information between the final publication and the protocol. The search was limited to studies published in English. No time restriction was applied.

Inclusion criteria in the present study were: systematic review articles that included quantitative meta-analyses of primary studies on the association between circulating TMAO concentrations and any of the outcomes specified above. The populations of interest were healthy adults (M and F), people at risk of the outcome at baseline, people with chronic kidney disease, people with a previous vascular or cerebral event (Table 1). The present study was concerned with the outcomes shown in Table 1 either as single or composite outcomes. All reported effect sizes such as relative risk (RR), odds ratio (OR), risk difference, and hazard ratio (HR) were qualified for inclusion in our review. In addition, systematic reviews/meta-analyses reporting mean difference or standardized mean difference of TMAO concentrations between people with and those without the outcomes were eligible for inclusion. The review team developed a list of potential confounders that could affect the associations under investigation in the present study.

We excluded animal and in-vitro studies, narrative reviews, meeting abstracts, and genomic studies. Studies reporting urinary TMAO were not eligible because the diagnostic value of urinary TMAO is not established at present. Studies including infants and pregnant or lactating women were excluded. Systematic reviews without quantitative data analysis were screened to identify primary studies, but they were not eligible for formal evaluation as a source of evidence in the present study.

According to our protocol, we extracted the following data into an excel sheet: first author, year, PMID, country of the corresponding author, study registration (where, when, registration ID), population, exposure, control, primary and secondary outcomes, number of reviewers, searched websites, end date of the search, search filters, inclusion and exclusion criteria, study designs of the primary studies, effect size of interest (document whether adjusted or none-adjusted), number of studies included, statistical model used for quantitative combination of the data (fixed-effect or random-effects model), pooled effect size per outcome and 95% Confidence Intervals (95%CI), heterogeneity results, main subgroup analysis, sensitivity analysis, results of publication bias, tools used to investigate study quality and funding sources/conflict of interest of the systematic reviews/meta-analyses. The results were summarized in descriptive tables that were reviewed to evaluate the body of evidence.

The literature search, screening, data extraction and the risk of bias assessment were conducted independently by 2 reviewers (RO and LM). The results were regularly discussed in the study meetings and disagreements between the reviewers were solved by discussion. Minor amendments to the protocol were documented during the entire review process. We planned to collect all primary studies, run an update search and conduct a robust quantitative meta-analysis focusing on subgroup analysis of adjusted effect sizes. This part of the work is currently in progress.

2.2. Risk of bias assessment

The risk of bias assessment was performed using individualized

AMSTAR 2 tool (A MeaSurement Tool to Assess systematic Reviews, [Supplemental Table 2](#)). The overall evaluation of the confidence in the evidence was conducted using the criteria shown in [Supplemental Table 2](#). A low confidence in the evidence can result from failure to meet goodness criteria of 6 pre-defined critical domains in AMSTAR 2; existing pre-study protocol, search strategy, transparency about excluded studies, risk of bias assessment, methods of statistical combination of the results, and publication bias.

3. Results

3.1. Search results and general evaluation

The initial search identified 92 potentially relevant articles in MEDLINE, 69 in Web of Science, and 313 in Cochrane library. After screening the titles and abstracts, 31 publications were eligible for full text screening. After excluding 4 publications ([Supplemental Table 3](#)), we included 27 systematic reviews/meta-analyses investigating the association between TMAO and stroke ($n = 7$), cardiovascular disease and cause-specific and all-cause mortality ($n = 14$), and other outcomes ($n = 6$) ([Table 2](#) and [Supplemental Tables 4 and 5](#)). No meta-analyses without systematic reviews were identified in our search. The study flow diagram is shown in [Fig. 1](#).

All systematic reviews/meta-analyses did not report whether a study protocol was prepared prior to conducting the study. Comparing the date of registering the protocol, that of literature search, and submission/publication date suggested that most authors registered the protocols after conducting the search or shortly before publishing. The 27 systematic reviews/meta-analyses included only observational studies on populations with existing clinical conditions that may both cause elevated TMAO and contribute to the etiology of the outcome in question. The systematic reviews/meta-analyses combined data of different study designs and for cohort studies the follow up duration ranged between days and years. Definition of elevated TMAO varied greatly between studies, thus it was not possible to establish a valid threshold for TMAO to define high risk populations.

Dealing with adjusted statistical measures was often unclear and heterogeneous. The majority of the systematic reviews/meta-analyses decided on the statistical combination of the data (fixed-effect or random-effects model) based on the observed heterogeneity (i.e., I^2 statistics), rather than on the hypothesized associations defined in the planning phase ([Supplemental Table 5](#)). Moreover, none of the systematic reviews/meta-analyses reported a list of excluded primary studies and justified the exclusions. The assessments of the quality of primary studies were not transparent in several systematic reviews/meta-analyses. The source of funding and conflict of interest statement were reported in 19 systematic reviews/meta-analyses ([Supplemental Table 6](#)), while none reported this information in the primary studies.

According to the AMSTAR 2 tool, all available systematic reviews/meta-analyses provided critically low confidence on the association between TMAO and the outcomes addressed in this umbrella review ([Supplemental Table 7](#)). Specific flaws in design, conduct and/or reporting are described in [Supplemental Table 8](#).

3.2. Stroke and related outcomes

The association between circulating TMAO concentrations and stroke was studied in 7 systematic reviews/meta-analyses [30–36], of which only 4 were registered in a public domain [31,32,35,36] ([Table 2](#) and [Supplemental Tables 4 and 5](#)). Despite similar questions, the studies were heterogeneous in their inclusion and exclusion criteria and search strategies ([Supplemental Table 4](#)). The primary studies on stroke were conducted in populations with existing comorbid risk factors for stroke or a previous stroke event ([Table 2](#)). All 7 systematic reviews/meta-analyses comprised different study designs and effect size measures (e.g., OR, RR, HR or a mix of those). Subgroup analysis by

				83.2) $\mu\text{mol/L}$. GFR ml/ (min.1.73m ²) in subjects with high TMAO vs. those with low TMAO MD = 12.9 (16.6, 9.14). Correlations between TMAO and GFR = -0.45 (-0.58, -0.32).

CC, case control study design; CHD, coronary artery disease; CKD, chronic kidney disease; CO, cohort study design; CS, cross sectional study design; CVD, coronary vascular disease; HF, heart failure; HR, hazard ratio; GFR, glomerular filtration rate; MACCE/MACE, major adverse cardiac and cerebrovascular event; MD, mean difference; MI, myocardial infarction; MRS, mendelian randomization studies; OR, odds ratio; mRS, modified Rankin scale; SMD, standardized mean difference.

study design was insufficient to draw any conclusion on temporality due to low number of studies [33].

Higher TMAO showed association with stroke or stroke-related outcomes (based on pooled estimates of OR, RR or HR > 1), while the strength of association varied between the systematic reviews/meta-analyses (Table 2). Publication bias was investigated using appropriate statistical or visual methods in 4 of the 7 systematic reviews/meta-analyses on stroke [31–33,35], of which 2 studies showed evidence for publication bias [32,33] (Supplemental Table 5).

3.3. Cardiovascular/cerebral, cause-specific- and all-cause mortality, and/or major adverse cardiovascular events

We identified 14 systematic reviews/meta-analyses addressing at least one outcome in this category [18,35,37–48] (Table 2, Supplemental Tables 4 and 5). The term “major adverse cardiovascular events (MACE)” was used in 10 studies, but the definitions of MACE were very heterogeneous and often included conditions such as heart transplant and heart failure [40,43–45] that are not considered to be cardiovascular diseases or all-cause mortality that could be due to non-cardiovascular diseases (Supplemental Table 9). The definition of MACE was also used as reported in the primary studies [37,39,42,47] without specifying the original definition of this composite outcome. In the same context, serious discrepancies were detected between the search terms and the intended outcomes of interest (Supplemental Table 9).

Eight of the 14 systematic reviews/meta-analyses were registered in a public domain [18,38,40–43,48,49] (Supplemental Table 4). Ten systematic reviews/meta-analyses included only prospective cohort studies of different follow up time [37,40,41,43–48] whereas; the remaining 4 included multiple study designs (Table 2). The populations in the primary studies were individuals with existing CVDs or CVD-risk factors (Table 2 and Supplemental Table 4). In general, almost all systematic reviews/meta-analyses reported higher HR, RR, or OR for MACE and all-cause mortality when circulating TMAO concentrations were higher. Only 6 of the 14 meta-analyses specified using an adjusted effect size in the data analysis [37,43–46,48], but the associations were generally similar across all studies irrespective of using adjusted estimates. The systematic reviews/meta-analyses were also heterogeneous with regard to their inclusion and exclusion criteria and statistical models used for data combination.

Three systematic reviews/meta-analyses did not investigate publication bias. Several systematic reviews/meta-analyses showed evidence suggesting significant publication bias [37,41,44,45], but only 2 systematic reviews/meta-analyses accounted for this bias (e.g., by performing trim-and-fill modelling) [41,45]. Only 9 systematic

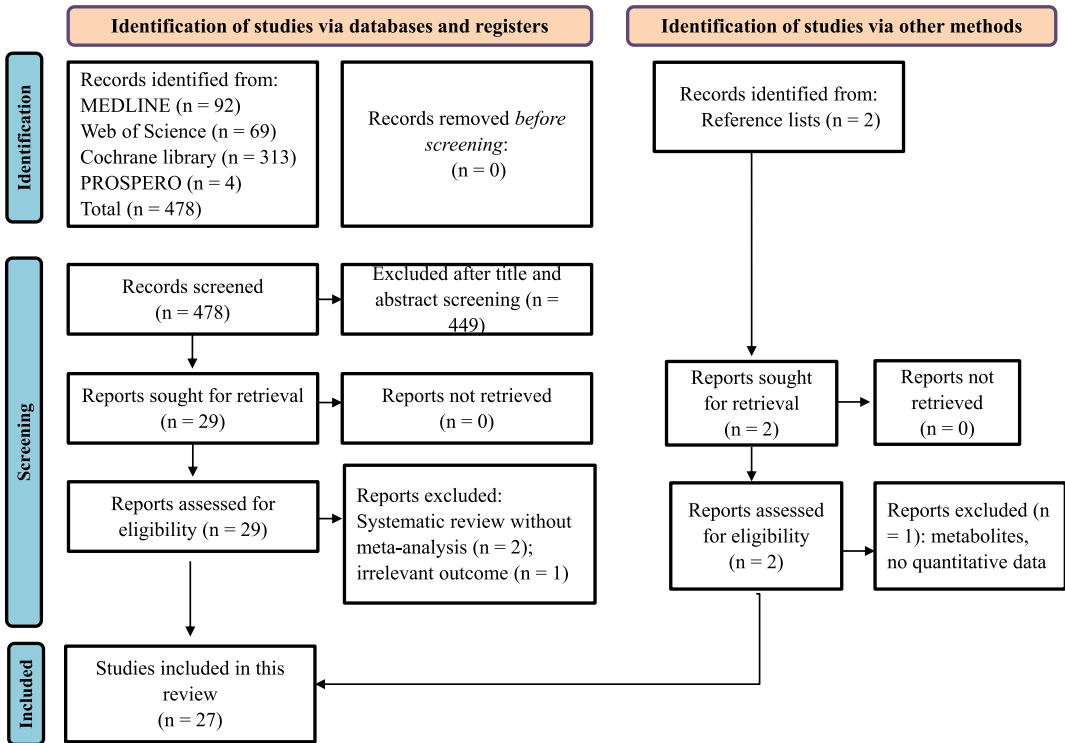

Fig. 1. Study flow diagram.

reviews/meta-analyses conducted subgroup analyses to identify sources of heterogeneity between the primary studies (Supplemental Table 5).

3.4. Other outcomes

Six additional systematic reviews/meta-analyses dealt with the associations between TMAO concentrations and hypertension [50], chronic kidney disease [51,52], heart failure [53], arterial fibrillation [54], or cardiometabolic risk [55]. Five of the 6 systematic reviews/meta-analyses were registered [50–52,54,55]. The primary studies were conducted among people with established illnesses.

Meta-analysis of 13 primary studies reported a moderate correlation between circulating TMAO and GFR [correlation coefficient (95%CI) = -0.45 (-0.58 , -0.32)] [52]. This correlation was markedly weak in studies among individuals without chronic kidney disease [56,57] compared to studies among people with chronic kidney disease [52], confirming that renal function is an important determinant of TMAO and a confounder in the association between TMAO and the investigated clinical outcomes.

4. Discussion

The association between TMAO and clinical outcomes related to vascular, cerebral, or renal diseases was addressed in 27 systematic reviews/meta-analyses of human observational studies. Careful evaluation of the systematic reviews/meta-analyses indicated a low confidence in the evidence due to issues related to design or conduct of the studies. All primary studies included populations with prevalent risk factors for future outcomes. The systematic reviews/meta-analyses combined data from different study designs (cohort, case-control, and cross sectional) and measures of associations, and applied different inclusion and exclusion criteria for similar questions. The low quality of systematic reviews/meta-analyses was due to methodological flaws and low quality of the included primary studies.

Elevated plasma concentration of TMAO has emerged as a potential predictive marker of disease outcomes in precision medicine, similar to eGFR. TMAO could also have an etiological role in some diseases as suggested by animal studies [25,26,28]. In clinical practice, the implications and interpretation of TMAO concentrations depend on whether TMAO is a cause of or a marker for the disease. If elevated plasma TMAO concentration in people at risk would predict disease outcomes, TMAO measurement would offer the possibility of intensifying the therapies to delay or prevent disease progression. In terms of hierarchy of evidence, a causal role of TMAO in diseases is not evident, as no randomized control trials have shown that lowering TMAO may reduce the risk of clinical outcomes. Lowering TMAO concentrations can be theoretically achieved by eliminating the gut bacterial strains that produce TMA, turning off the FMO3 enzyme and thereby, reducing the conversion of TMA to TMAO, or cutting all dietary sources of TMA precursor such as choline, betaine and carnitine (including food supplements). Whether interventions to lower TMAO show protective or deleterious health effects in humans is currently unknown. On the one hand, interventions with probiotics [58,59] or symbiotics [60] (that aimed to cause a beneficial shift in the microbiome) failed to lower TMAO. On the other hand, trials that found a minor reduction of plasma TMAO concentrations failed to show improvements in surrogate markers of atherosclerosis such as blood lipids [61,62].

In the absence of randomized controlled trials of suitable design and duration, observational studies on biomarkers such as TMAO are insufficient to establish a causal relationship due to inherent limitations [63]. First, elevated TMAO concentrations could be caused by the outcome (reverse causality), e.g., poor kidney function resulting in reduced TMAO clearance and higher circulating concentrations. Second, confounding by shared causes of elevated TMAO and the outcome could exist (e.g., meat consumption or kidney dysfunction). Third, the criteria of including/excluding participants into the study (selection bias) could

bias observed effects. Fourth, imprecision in assessments of the outcome, the confounding factors, or TMAO concentrations can lower confidence in the associations. Almost all primary studies measured plasma TMAO concentrations only once and mostly in people with acute or chronic diseases. Studies on patients with ischemic stroke collected blood samples for measuring TMAO in the acute phase of the disease (i.e., within 24 h of hospital admission) [64,65]. However, repeated-measurement studies have shown that TMAO concentrations decline a few days after ischemic stroke [66,67], thus questioning the relevance of the baseline TMAO measurement as a determinant of the clinical outcome in people admitted to the hospital with stroke.

Several confirmatory systematic reviews/meta-analyses on TMAO overlap with regard to the aim, outcomes, populations, methods and results. In contrast, there is a lack of systematic reviews/meta-analyses on TMAO precursors such as choline, betaine and carnitine since they are considered analogue exposures, and might be expected to show the same associations with the outcomes as with TMAO.

In conclusion, the associations between TMAO and the outcomes of this umbrella review were investigated in 27 systematic reviews/meta-analyses, but the evidence remains insufficient to determine the nature of the association, due to low quality of the studies, variability in adjustment for critical confounding factors, inclusion of participants at high risk for the outcome of interest, variability of follow up time in cohort studies, and lack of a biological threshold for TMAO to define high risk populations. Due to lack of randomized controlled trials, it remains unclear if elevated TMAO is the result of renal dysfunction, a proxy for other causal predictors of the clinical outcomes of interest, or whether it plays an etiological role in the progression of the disease.

Data availability statement

Data was extracted from the original systematic reviews/meta-analyses and summarized in the present article and therefore, data will not be shared beyond this publication.

Disclosures

RO has served on advisory board for Balchem Corporation. LM, BAW, GH, IE, JG, and RCC have no conflict of interest to declare.

Funding

Financial support was provided by a grant from Balchem Corporation, US (granted for RO). Balchem Corporation had no role in study design, the collection, analysis and interpretation of data, the writing of the report; or in the decision to submit the article for publication.

Appendix A. Supplementary data
